Global Mapping of the Inc-Human Interactome Reveals that Retromer Restricts *Chlamydia* Infection

**Highlights**

- *Chlamydia* inclusion membrane (Inc)-human protein interactions were identified by AP-MS

- Bacterial and viral pathogens share human protein targets

- IncE directly binds the PX domains of retromer components SNX5 and SNX6

- Retromer restricts *Chlamydia* infection and promotes inclusion tubulation

**In Brief**

*Chlamydia* inclusion membrane proteins are uniquely positioned at the host-pathogen interface, but their host targets are largely unknown. Mirrashidi et al. report a *Chlamydia*-human protein-protein interactome that identifies host proteins and pathways implicated in pathogenesis. They show that *Chlamydia* sequesters retromer components to potentially overcome host mechanisms of pathogen restriction.
Global Mapping of the Inc-Human Interactome Reveals that Retromer Restricts Chlamydia Infection

SUMMARY

Chlamydia trachomatis is a leading cause of genital and ocular infections for which no vaccine exists. Upon entry into host cells, C. trachomatis resides within a membrane-bound compartment—the inclusion—and secretes inclusion membrane proteins (Inc) that are thought to modulate the host-bacteria interface. To expand our understanding of Inc function(s), we subjected putative C. trachomatis Inc to affinity purification-mass spectrometry (AP-MS). We identified Inc-human interactions for 38/58 Incs with enrichment in host processes consistent with Chlamydia’s intracellular life cycle. There is significant overlap between Inc targets and viral proteins, suggesting common pathogenic mechanisms among obligate intracellular microbes. IncE binds to sorting nexins (SNXs) 5/6, components of the retromer, which relocates SNX5/6 to the inclusion membrane and augments inclusion membrane tubulation. Depletion of retromer components enhances progeny production, revealing that retromer restricts Chlamydia infection. This study demonstrates the value of proteomics in unveiling host-pathogen interactions in genetically challenging microbes.

INTRODUCTION

Intracellular pathogens that replicate within a membrane-bound compartment employ secreted virulence factors to subvert the host and facilitate survival. Decoding these interactions has been especially difficult for genetically challenging organisms, such as Chlamydiae. These obligate intracellular pathogens are important causes of human disease for which no effective vaccine exists. C. trachomatis is the major cause of noncongenital blindness worldwide and a leading cause of sexually transmitted diseases and noncongenital infertility in Western countries (Mandell et al., 2010). C. pneumoniae is an important cause of respiratory infections and is linked to a number of chronic diseases (Leonard and Borel, 2014). Although treatable with antibiotics, no drug is cost effective enough for widespread elimination of disease in developing nations.

All Chlamydiae share a common intracellular life cycle, alternating between an infectious, spore-like elementary body (EB) and a noninfectious, metabolically active reticulate body (RB) (reviewed in Bastidas et al., 2013). Upon entry into nonphagocytic cells, the EB resides within a membrane-bound compartment—the inclusion—and quickly diverges from the canonical endolysosomal pathway. The EB differentiates into an RB and replication commences. After replicating within the ever-enlarging inclusion over 24–72 hr, the RB differentiates to an EB and is then released, ready to infect neighboring cells.

How Chlamydia establishes its replicative niche is incompletely understood. Chlamydia manipulates the actin cytoskeleton and microtubule-based motors; obtains nutrients; interacts with numerous host cell organelles; and inhibits the innate immune system, autophagy, and programmed cell death (Bastidas et al., 2013). However, the Chlamydia factors and host cell proteins that mediate these events are largely unknown.

Despite their small genome size, Chlamydia are estimated to encode a disproportionate number of secreted virulence effectors, ~10%–15% of their genome (Betts-Hampikian and Fields, 2010). A large subset of effectors, termed inclusion membrane proteins (Inc), are translocated by the type III secretion system and inserted into the inclusion membrane (Moore and Ouellette, 2014). Their defining feature is the presence of one or more unilobed domains, typically composed of two closely spaced transmembrane regions separated by a short loop (Bannantine et al., 2000) (Figure 1A). Once inserted into the inclusion membrane, Incs are predicted to extend their termini into the host cytoplasm (Rockey et al., 2002), ideally positioning them at the host-pathogen interface. Given the only recent and
limited ability to genetically modify Chlamydia, a detailed understanding of the roles of Incs during infection has been challenging. Indeed, only a few host-binding partners of Incs have been identified (Moore and Ouellette, 2014). Furthermore, Incs share little homology to each other or to known proteins, providing limited insight to their functions (Dehoux et al., 2011; Lutter et al., 2012).

We used large-scale AP-MS to comprehensively identify protein-protein interactions (PPIs) between C. trachomatis Incs and the host proteome to decode mechanisms by which this pathogen establishes its privileged intracellular niche. Our analysis has uncovered a wealth of previously unidentified Inc-host interactions. We analyzed in detail the interaction between IncE, an early expressed Inc of unknown function, and the SNX-BAR proteins, a subset of retromer components. We found that IncE directly binds the PX domains of SNX5/6, that IncE is sufficient to disrupt retromer trafficking, and that retromer restricts C. trachomatis infection. Our study underscores the power of using comprehensive proteomics to study host-pathogen interactions, particularly for genetically challenging organisms such as Chlamydia.

RESULTS

AP-MS Identifies High-Confidence Inc-Human PPIs

We cloned nearly all (58) of the 62 predicted C. trachomatis Incs (Dehoux et al., 2011; Lutter et al., 2012) from two C. trachomatis orfeomes (Roan and Starnbach, 2006; Sisko et al., 2006), including the full-length proteins and/or the predicted cytoplasmic domains. Twenty-four of these Incs are evolutionarily conserved among five or more Chlamydia species (“core” Incs) (Dehoux et al., 2011; Griffiths et al., 2006; Lutter et al., 2012). A total of 78 Inc constructs were fused to Strep tags, transiently expressed in HEK293T cells, and affinity purified (AP) over Strep-Tactin beads. Entire eluates were subjected to MS (Figure 1B). All APs were performed in at least triplicate and confirmed by immunobloting with an anti-Strep antibody and silver staining (data not shown). From over 250 AP-MS runs, we identified 30,924 PPIs (see Table S1 available online), representing 3,982 unique human proteins.

A set of high-confidence PPIs was established by analyzing the complete data set using two algorithms: MiST (Jäger et al., 2012) and CompPASS (Sowa et al., 2009) (Table S1). Using stringent criteria (MiST score ≥ 0.7 or the top 1% of CompPASS scores), we identified 354 high-confidence Inc-human PPIs, representing 335 unique host binding partners for 38/58 Incs (Table S1; Figure S1). Importantly, IncD and CT228 coeluted their prey with previously published AP-MS interactomes of HIV (Jäger et al., 2012), HCV (Ramage et al., 2015), and KSHV (Davis et al., 2015). p values were determined by the hypergeometric test. See also Figure S1, Table S1, and Table S3.

Constructing a Comprehensive Inc-Human PPI Network

We assembled an Inc-human PPI network using two databases of known human-protein interactions (CORUM [Ruepp et al., 2010] and STRING [Franceschini et al., 2013]) to identify multiprotein complexes and potential connections between Incs (Figure 2). Within this subset, we found individual Incs that associate with several members of multiprotein complexes, including retromer, COP9 signalosome, condensin II, GINS, and dynactin. We also observed numerous examples of two or more individual Incs that interact with the same host complex. For example, five Incs (CT005, CT556, CT195, CT058, and CT819) interacted with members of the TIM-TOM complex.
host machinery responsible for mitochondrial protein import (Bauer et al., 2000). Three Incs (CT135, CT565, and CT357) each bind to different subunits of vacuolar ATPases, multiprotein enzymes that control acidification of intracellular organelles (Marshansky and Futai, 2008). We also identified several Incs that target proteins involved in ubiquitination, consistent with a recent report that C. trachomatis remodels the host proteome (Olive et al., 2014). Finally, we found a subset of host proteins (RTN4, VKORC1L1, CPVL, LRRC59, WDR6, VPRBP, and RNH1) that were each targeted by two individual Incs, suggesting that modulating these targets may be critical for Chlamydia’s intracellular survival.

Figure 2. Network Representation of the Inc-Human Interactome
The high-confidence Inc-host network contains 38 Inc proteins (core Incs, dark gray; non-core Incs, light blue), and 335 unique human prey (light gray). Inc-human interactions (blue lines) were identified by AP-MS. Interactions between human proteins (dark gray lines) were curated from CORUM and STRING databases. Inc-human prey in common with HIV, KSHV, or HCV prey (Davis et al., 2015; Jäger et al., 2012; Ramage et al., 2015) are outlined in red. A subset of identified host complexes or proteins with similar functions are labeled. See also Table S2.
The Inc-Human Interactome Predicts Inc Functions during Chlamydia Development

Analysis of the entire data set with gene ontology (GO) and protein database (KEGG and PFAM) terms revealed that Inc-host protein interactions were enriched for many compartments and pathways consistent with Chlamydia’s intracellular life cycle (Figures 3, S2, and S3; Table S2). For example, we found increased representation for host proteins that localize to the ER, Golgi, mitochondria, endosomes, lysosomes, and actin cytoskeleton, all of which associate with the C. trachomatis inclusion (Bastidas et al., 2013). We also identified host targets enriched for biological processes and molecular functions known to be modulated during infection, such as endocytosis, ubiquitination, apoptosis, cell cycle/division, and DNA damage/repair (Bastidas et al., 2013).

Our analysis uncovered cellular processes that may be modulated by Chlamydia, such as chromosome condensation (Condensin II complex), splicing (SMN complex), retromer trafficking (SNXs), and actin cytoskeleton, all of which associate with the C. trachomatis inclusion (Bastidas et al., 2013). We also identified host targets enriched for biological processes and molecular functions known to be modulated during infection, such as endocytosis, ubiquitination, apoptosis, cell cycle/division, and DNA damage/repair (Bastidas et al., 2013).

Our analysis uncovered cellular processes that may be modulated by Chlamydia, such as chromosome condensation (Condensin II complex), splicing (SMN complex), retromer trafficking (SNXs), and the cytosolic surveillance response (DNA/RNA sensors) (Figures 2, S2, and S3; Table S2). Our PPI data set allows us to now link specific Incs to host cell processes important for infection (Figure 3).

Chlamydial and Viral Effectors Share Host Protein Targets

To determine whether diverse intracellular pathogens target host proteins in common with each other, we compared our Inc-human interactome to three recently assembled virus-human interactomes: HIV (Jäger et al., 2012), KSHV (Davis et al., 2015), and HCV (Ramage et al., 2015). These viral interactomes were derived using the same pipeline that we employed, providing an opportunity for cross-pathogen analyses. We found a significant overlap in high-confidence prey between Chlamydia and each of the three viruses (Figure 1C; Table S3). We identified 98 high-confidence C. trachomatis prey shared with one or more viruses, 10 shared with 2 or more viruses, and 2 shared with all 3 viruses (Figure 1D). Host complexes or pathways targeted by Chlamydia and one or more viruses included lysosomal ATPases, DNA repair, the TIM-TOM complex, the dynactin complex, the ubiquitin machinery, and Golgi trafficking (Figure 2). Strikingly, we found core Incs were more likely to overlap with viral targets compared to non-core Incs (p < 0.001; Figure 1E; Table S3).

IncE Interacts with Retromer-Associated Sorting Nexins

Our interactome revealed that IncE was enriched for retromer-associated proteins, including SNX1, SNX2, SNX5, and SNX6 (SNX1/2/5/6) (Figures S2 and 2; Table S2). IncE, located in an operon together with IncD, IncF, and IncG, is expressed within the first 2 hr of C. trachomatis infection (Scidmore-Carlson et al., 1999), but its function(s) and host binding partners were unknown. The retromer complex is composed of the vacuolar protein sorting (VPS) trimer and a heterodimer of SNX-BAR proteins, SNX1/2-SNX5/6 (Cullen and Carlton, 2012; Teasdale and Collins, 2012). SNX-BAR proteins are comprised of a phosphoinositide-binding Phox homology (PX) domain, which functions in endosomal membrane trafficking, membrane remodeling, and organelle motility (Cullen and Korswagen, 2012; Seaman, 2012), and a Bin-amphiphysin-Rvs (BAR) domain, which both senses and induces membrane curvature (Teasdale and Collins, 2012). By inducing tubulation and then recruiting additional factors that lead to scission and...
formation of vesicles, the retromer SNX-BARS facilitate sorting of protein receptors between endosomes and the trans-Golgi network (Cullen and Carlton, 2012; Seaman, 2012). All four retromer SNX-BARs (SNX1/2/5/6) were identified as very-high-confidence targets of IncE (MiST > 0.96; top 0.002% of CompPASS) (Table S1).

We confirmed that IncE interacts specifically with retromer SNX-BARs in vivo. Endogenous retromer SNX-BARs coaffinity purified with transiently expressed IncE, but not IncD, IncF, or IncG (Figures 4A and S4A). In C. trachomatis-infected cells, IncE coimmunoprecipitated with endogenous SNX6 (Figure 4B) or with transfected FLAG-SNX5, but not transfected FLAG-SNX14 (Figure 4C), revealing that IncE specifically binds SNX5/6 in vivo.

We tested informative deletion mutants of IncE-Strep (Figure 4D) by transient expression in HEK293T cells and found that only mutants containing the IncE C-terminal cytoplasmic domain (IncE101–132) coaffinity purified with retromer SNX-BARs (Figures 4E and S4B). AP-MS of IncE101–132 also identified retromer SNX-BARs as the highest confidence PPIs (Table S1). Finally, IncE101–132-EGFP colocalized with endogenous SNX1, SNX2, SNX6, and transiently expressed FLAG-SNX5 in endosomes, as visualized by confocal microscopy (Figure S4C). Together, these results show that IncE101–132 is both necessary and sufficient to interact specifically with retromer SNX-BARs.

**IncE101–132 Binds Directly to the PX Domains of SNX5 and SNX6**

To determine whether IncE101–132 binds directly to one or more retromer SNX-BARs, we performed in vitro pull-downs with 6xHis-MBP-IncE-Strep and 8xHis- or 6xHis-MBP-SNXs individually purified from E. coli. IncE101–132 directly bound to the PX domains of SNX5 and SNX6, but failed to bind the corresponding PX domains of SNX1 or SNX2. The C-terminal cytoplasmic domain of IncD, IncD95–141, did not bind the PX domains of retromer SNX-BARs (Figure 4F). Neither IncE101–132 nor IncD95–141 bound the BAR domains of retromer SNX-BARs in vitro.
Thus, IncE101–132 is sufficient to bind SNX5/6 PX domains in the absence of other human proteins. PSIPRED protein sequence analysis revealed that IncE101–132 contains a putative β-hairpin structure (Figure S4E). In vitro pulldowns of IncE101–132 truncations (Figure S4E) demonstrated that the β-hairpin region was required for SNX5 binding (Figure S4F), suggesting that this secondary structure may play a role in the direct binding of IncE to SNX5/6.

Retromer SNX-BARs Colocalize with IncE on the Inclusion Membrane

Retromer SNX-BARs primarily colocalize with PtdIns(3)-rich endosomal membranes (Cullen and Carlton, 2012; Seaman, 2012). Confocal microscopy of C. trachomatis-infected cells stained with antibodies to SNXs and to IncE revealed that at 6 and 24 hr postinfection (hpi), endogenous SNX1, SNX2, SNX6, and transfected FLAG-SNX5 colocalized with IncE on the inclusion membrane (Figures 5A, S5B, and S5C; data not shown). We also observed IncE on tubules emanating from inclusions that were positive for SNX1, SNX2, FLAG-SNX5, SNX6, and IncA (Figures 5A and S5A–S5C). In contrast, SNX27, a retromer-associated SNX involved in endosome-to-plasma membrane cargo recycling (Lauffer et al., 2010), was not recruited to the inclusion, but instead remained localized in punctate structures (Figures 5B). Thus, Chlamydia inclusions and tubules specifically associate with retromer SNX-BARs.

Retromer functions in trafficking cargo-containing vesicles along microtubules to the trans-Golgi through the interaction of SNX6 with dynactin subunit 1 (Hong et al., 2009). To determine whether Chlamydia inclusion tubulation requires microtubule polymerization, infected cells were exposed to nocodazole, and tubules were examined by confocal microscopy. Microtubules were required for the formation of SNX and IncE-positive tubules at 6 hpi (Figure S5B) and 24 hpi (Figure S5C). However, microtubule polymerization was not required for SNX recruitment to inclusions (Figures S5B and S5C), consistent with our results demonstrating that IncE directly binds to and likely recruits SNX5/6 to the inclusion.
Chlamydia Inclusions Do Not Stably Associate with the VPS Subcomplex

In addition to SNX heterodimers, retromer also contains the tripartite cargo recruitment complex composed of VPS26A, VPS29, and VPS35 (Seaman, 2012). While retromer SNX-BARs co-affinity purified with IncE, the VPS subunits and other retromer-associated SNXs were notably absent (Table S1; Figure 4E). Confocal microscopy of C. trachomatis-infected cells demonstrated that, in contrast to the robust recruitment of SNX-BARs to the inclusion membrane, VPS35 (Figure 5C) and GFP-VPS29 (data not shown) remained in punctate structures. Chlamydia infection significantly diminished SNX1 localization to VPS35-positive compartments (Figure S6D, p < 0.0001), while total protein levels were unchanged (Figure S5E), suggesting that Chlamydia relocates SNX-BARs from endosomes to the inclusion membrane.

SNX1 is recruited to early Salmonella-containing vacuoles (SCVs) (Bujny et al., 2008), so we assessed whether other retromer components are recruited to SCVs. We confirmed SNX1 recruitment (Figure S5F) and also found that SNX2 and VPS35 clearly decorated SCVs and associated tubules (Figures S5G and S5H). Thus, in contrast to endosomal membrane tubules or SCVs, Chlamydia inclusions and tubules do not maintain a stable association with the VPS complex.

IncE Is Sufficient to Recruit Retromer SNX-BARs and Induce Inclusion Tubulation

BAR domain-containing proteins form a helical coat, which impose membrane curvature and remodel membranes into tubular profiles (Frost et al., 2008). Based on our observation that retromer SNX-BARs colocalized with IncE on Chlamydia inclusion membrane tubules, we predicted that overexpression of IncE would be sufficient to enhance inclusion tubulation. Therefore, we transformed C. trachomatis serovar L2, a strain with lower baseline levels of tubulation compared to serovar D, with plasmids engineered to express C-terminally FLAG-tagged IncE (pTet-IncE-FLAG) or IncG (pTet-IncG-FLAG) under a tetracycline (Tc)-inducible promoter. As expected, upon induction with Tc, IncE-FLAG and IncG-FLAG were readily detected on the inclusion membrane and tubules (Figure 6A). Importantly, induction of IncE-FLAG was sufficient to enhance recruitment of SNX6 to the inclusion (Figures 6B and 6C) and to enhance formation of IncA-positive (Figure S6A) and SNX6-positive (Figure 6C) tubules compared to IncG-FLAG or uninduced controls. We also observed increased SNX6 recruitment and SNX6-positive tubules in C. trachomatis transformed with a vector expressing untagged IncE (pIncE) under control of its native promoter compared to C. trachomatis transformed with empty vector (Figures 6D and 6E). IncE expression in C. trachomatis-transformed strains was verified by immunoblot analysis (Figures S6B and S6C). We conclude that IncE expression is sufficient to enhance SNX6 inclusion recruitment and inclusion tubulation.

We used siRNA depletion to determine if retromer function is required for inclusion tubulation. Due to functional redundancy of retromer SNX-BARs (Seaman, 2012), we simultaneously depleted cells of SNX1 and SNX2, SNX5, and SNX6; all four SNXs; or VPS35 (Figure S6D). Depletion of any retromer component decreased both the length and number of inclusion tubules (Figures 6F and S6E), consistent with our model that recruitment of SNX-BARS enhances inclusion tubulation.

IncE Disrupts Retromer-Dependent Trafficking of the Cation-Independent Mannose-6-Phosphate Receptor

Since IncE bound SNX5/6 in vitro (Figure 4F), and C. trachomatis infection caused relocalization of SNX5/6 from endosomes to the inclusion membrane (Figures 5A), we tested whether IncE could interfere with retromer-dependent trafficking. For these experiments, we transfected cells with IncE101–132-EGFP, or, as a control, IncD95–141-EGFP, and analyzed localization of the retromer trafficked cation-independent mannose-6-phosphate receptor (CI-MPR), a well-established assay for retromer function (Arighi et al., 2004; Wassmer et al., 2007). Compared to untransfected cells or transfection with IncD95–141, transfection with IncE101–132-EGFP changed the distribution of CI-MPR from juxtanuclear TGN46-positive compartments to a more disperse collection of large vesicles (Figure 7A). Concomitantly, there was decreased colocalization between CI-MPR and TGN46 (Figure 7B). Instead, CI-MPR largely overlapped with VPS35 and IncE101–132-EGFP (Figure 7C), indicating that IncE101–132-EGFP expression is sufficient to maintain CI-MPR in retromer-containing compartments, thereby disrupting efficient CI-MPR trafficking to the trans-Golgi.

Retromer SNX-BARS Restrict C. trachomatis Infection

As IncE101–132 expression altered retromer trafficking, we tested the hypothesis that retromer may be detrimental to C. trachomatis infection. Depletion of SNX5/6 or all four retromer SNX-BARS significantly enhanced production of infectious progeny (Figure 7D), suggesting that retromer SNX-BARS restrict C. trachomatis infection. While we observed a trend toward enhanced progeny with VPS35 depletion, it did not reach statistical significance (p = 0.0574). Enhanced progeny could not be explained by an increase in primary infection; in fact, we noted a significant decrease in primary inclusion formation upon SNX1/2 depletion (Figure 7E). Thus, SNX1/2 may participate in early stages of infection, which could explain the more modest effect of SNX1/2 depletion on infectious progeny production (Figure 7D). Altogether, our results support a model (Figure S7) whereby IncE directly binds SNX5/6, which redirects the retromer SNX-BAR subcomplex to the inclusion membrane, with two functional consequences. First, recruitment of SNX-BARS induces inclusion membrane tubulation, likely through the well-studied ability of BAR domain proteins to induce membrane curvature. Second, by sequestering SNX-BARS at the inclusion and potentially disrupting retromer function, C. trachomatis relieves the restriction that retromer imposes on infection.

DISCUSSION

Assigning functions to individual Chlamydia effectors has been difficult in the absence of robust genetic approaches. In this study, we applied an unbiased systematic AP-MS approach to comprehensively identify putative host targets of Incs, effectors that are ideally poised to orchestrate host-pathogen interactions. Our work is especially valuable because very few Inc targets had been identified.
Figure 6. IncE Is Sufficient to Enhance SNX-BAR Recruitment and Inclusion Tubulation

(A–C) HeLa cells were infected with C. trachomatis serovar L2 transformed with pTet-IncE-FLAG or pTet-IncG-FLAG. As indicated, Tc was added at 1 hpi. At 20 hpi, cells were analyzed by confocal microscopy for (A) FLAG or (B and C) SNX6. (A and B) Maximal intensity projections of 0.2 μm z slices. (C) shows maximal intensity projections and single XY slices from the boxed region in (B). Scale bar, 10 μm.

(D and E) HeLa cells were infected with C. trachomatis serovar L2 transformed with empty vector or pIncE. At 15 hpi, cells were fixed and stained with anti-SNX6, IncE, and DAPI. (E) shows enlargement of boxed region of (D). All images are maximum intensity projections. Scale bar, 10 μm.

(F) Quantitation of inclusion tubules per cell (dark gray bars) and length of the longest tubule per cell (light gray bars) (μm) in C. trachomatis-infected HeLa cells depleted of the indicated retromer components by siRNA. Data are mean ± SEM from three independent experiments. *p < 0.001 compared to corresponding control, unpaired (two-tailed) t test. See also Figure S6.
As with any AP-MS approach, false positives and false negatives are unavoidable. We employed two stringent scoring algorithms, MIST and CompPASS, to minimize false positives. Technical limitations of AP-MS may lead to false negatives (Verschueren et al., 2015), which could explain our failure to identify the following interacting partners: 14-3-3 and IncG (Scidmore and Hackstadt, 2001), Rab4 and CT229, (Rzomp et al., 2006), or VAMPs and IncA (Delevoye et al., 2008). Our inability to identify high-confidence PPIs for ~1/3 of Incs could be explained if (1) the Inc serves a structural role in the inclusion membrane (Mital et al., 2013), (2) the host target is a lipid (Mital et al., 2013), or (3) multiple Incs function together to form a binding interface (Gauliard et al., 2015; Mital et al., 2010).

Importantly, some putative Incxs have not been observed on the inclusion membrane at 24 hpi (Dehoux et al., 2011; Li et al., 2008; summarized in Table S1); however, their localization may be stage, cell type, or serovar specific. Of the 20 Incs whose membrane localization has been experimentally verified (Dehoux et al., 2011; Li et al., 2008), we identified high-confidence host targets for 15 Incs (75%) and validated two published Inc-host interactions (Derré et al., 2011; Lutter et al., 2013). Overall, this Inc-host interactome allows us to link host processes to specific Incs and identifies a plethora of Inc-human interactions of significant biological interest that merit further investigation.

Our standardized AP-MS pipeline provides an unprecedented opportunity to learn whether diverse intracellular pathogens use common strategies to survive. Not only did we observe a significant overlap between the interactomes of C. trachomatis and three human viruses, but we found that the more evolutionarily conserved core Incs are more likely to share host targets with viral effectors. Comparison of the overlap among all four pathogens revealed two common targets, MSH2 and UBE2O, suggesting that these host proteins may be critical for intracellular pathogen survival. Modulating UBE2O, one of ~35 human E2 ubiquitin ligases, is particularly intriguing, as it may be an efficient way for intracellular pathogens to regulate the stability of a distinct subset of host proteins.

Our Inc-human PPI network reveals an interaction between IncE and retromer SNX-BARs, which are involved in tubular-based endosomal trafficking (Seaman, 2012). SNX-BAR recruitment to membranes typically involves binding of SNX-PX domains to endosome-specific PtdIns(3)P (Cullen and Carlton, 2012; Seaman, 2012). Our work suggests that SNX5/6 bind directly to IncE independently of phosphoinositides and that the predicted IncC-terminal β-hairpin is required. Our findings expand the emerging concept that PX domains function not only as lipid recognition modules but also as PPI domains (Teadsdale and Collins, 2012). While the molecular details of the IncE-SNX5/6 interaction await further investigation, we note that SNX5/6 contain a unique double PXXP motif with an adjacent ~30 amino acid insertion that forms a long helical hairpin (Koharudin et al., 2009), which distinguishes SNX5/6 from SNX1/2. This feature may contribute to the recognition of SNX5/6 by IncE.

We examined processing and release of cathepsin D, a secreted lysosomal protease that is missorted when retromer trafficking is disrupted (Rojas et al., 2008). We were unable to demonstrate robust intracellular accumulation of the incompletely processed forms (our unpublished data), as reported upon depletion of VPS26 or Rab7 (Rojas et al., 2008), which could be explained if Chlamydia also alters secretory pathways. We do show that ectopic expression of IncE101-132, which does not appear to bind cargo (Table S1), alters CI-MPR localization in a manner similar to what is observed upon SNX5/6 depletion (Wassmer et al., 2007).

We observed a profound increase in infectious progeny production upon SNX5/6 depletion, which we postulate recapitulates IncE-mediated recruitment of the SNX-BAR complex away from retromer-containing compartments to the inclusion membrane. As primary inclusion formation was not enhanced, we predict that SNX5/6 restricts Chlamydia infection at later steps in the life cycle, such as replication, RB to EB conversion, EB escape, or EB infectivity. While the mechanism by which SNX5/6 restricts bacterial development is not clear, it could be through retromer-dependent or retromer-independent pathways. For example, retromer trafficking may contribute to the recognition or clearance of Chlamydia. Alternatively, since retromer is required to maintain the integrity of the trans-Golgi (Wassmer et al., 2007), IncE-mediated sequestration of retromer SNX-BARS may promote Golgi fragmentation, a process that facilitates lipid acquisition by C. trachomatis and enhances progeny production (Heuer et al., 2009). Finally, SNX5/6 may have other roles outside of retromer trafficking (Sun et al., 2013) that contribute to Chlamydia restriction.

Our results provide mechanistic insights into the formation of Chlamydia inclusion tubulation. We demonstrate that IncE and SNX-BARS colocalize on the inclusion membrane and tubules, that ectopic expression of IncE is sufficient to induce inclusion tubulation, and that depletion of retromer components limits inclusion tubulation. The direct recruitment of BAR-domain-containing proteins to the inclusion membrane provides a mechanistic link to tubulation, as these proteins are necessary and sufficient for membrane deformation and endosomal tubule formation (Frost et al., 2009). While the role of the tubules is not entirely understood, they are proposed to play a role in secondary inclusion formation (Suchland et al., 2005). We demonstrate that inclusion tubulation and infectious progeny production can be uncoupled: SNX5/6 depletion, which abrogates tubulation, leads to increased infectious progeny.

Our work highlights the strategies employed by diverse intracellular pathogens to repurpose retromer. Silencing of retromer components abrogates HIV (Groppelli et al., 2014), HPV (Lipovsky et al., 2013), Coxiella (McDonough et al., 2013), and Salmonella (Bujny et al., 2008) infections. Our finding that VPS35 is readily recruited to SCVs reveals that Salmonella recruits the VPS complex in addition to retromer SNX-BARS. In contrast, Chlamydia IncE selectively recruits retromer SNX-BARS without stably recruiting VPS components or SNX27. Interestingly, through an entirely different mechanism, Legionella also dissociates retromer subcomplexes by sequestering VPS components and blocking SNX-PtdIns(3)P binding (Finsel et al., 2013).

In summary, we have applied AP-MS to create a global network of C. trachomatis Inc-host PPIs, providing a...
Figure 7. IncE101–132-EGFP Disrupts Retromer Trafficking, and Retromer Depletion Restricts *C. trachomatis* Infection

(A) Localization of endogenous CI-MPR is perturbed in HeLa cells transiently transfected with IncE101–132-EGFP, but not IncD95–141-EGFP, compared to un-transfected (UT). Cells were fixed and stained with antibodies to TGN46, CI-MPR, and costained with DAPI. Shown are single z slices from confocal images. Scale bar, 10 μm.

(B) Quantitation of TGN46 colocalization with CI-MPR in cells expressing IncE101–132-EGFP or IncD95–141-EGFP. Mean Pearson's correlation coefficients from two independent experiments (n = 24 cells per experiment). *p < 0.05 compared to UT or IncD, using one-way ANOVA, post hoc Tukey's test.

comprehensive bacterial effector-host interactome. Our analysis has uncovered a wealth of previously unidentified Chlamydia Inc-host interactions. By linking individual Incs to specific host processes, our work, in conjunction with the development of genetic tools to generate targeted null mutants in Chlamydia (Johnson and Fisher, 2013), sets the stage to test the functional role of Incs. This methodology has broad applicability to the study of pathogenesis and is equally effective for identifying the targets of both membrane-bound and soluble effectors. We have uncovered overlapping and potentially druggable pathways targeted by viral and bacterial pathogens. Finally, investigation of the IncE-SNX5/6 interaction may provide insight into retromer biology.

EXPERIMENTAL PROCEDURES

Cell Culture, Transformations, and Bacterial Propagation

HeLa and HEK293T cells were maintained under standard conditions. C. trachomatis serovar D and L2 were propagated as previously described (Elwell et al., 2011). Chlamydia transformations were performed as previously described (Agassie and Derré, 2013; Wang et al., 2013).

Affinity Purification and Mass Spectrometry

Affinity purifications were performed as previously described (Jäger et al., 2012). Eluates were processed, trypsin digested, and concentrated for LC-MS/MS. Digested peptide mixtures were analyzed on a Thermo Scientific Velos Pro ion trap MS system equipped with a Proxeon Easy nLC II high-pressure liquid chromatography and autosampler system.

Scoring and Analyzing the Inc-Host Interactome

AP-MS samples were scored with CompPASS (Sowa et al., 2009) and MiST algorithms, using MiST weights optimized for the KSHV-host interactome (Davis et al., 2015). The scored data set included a subset of Chlamydia secreted effectors that will be published independently. All bait-prey pairs with a MiST score ≥ 0.70 or the top 1% of the CompPASS WD scores were combined with human protein interactions from CORUM and STRING databases that connect prey. The resulting network diagram was plotted using Cytoscape, v.3.1.2 (Smoot et al., 2011). All scored preys were queried against GO, KEGG, and PfAM ontologies for functional and domain annotations. Terms were manually curated, and baits were analyzed for significantly enriched terms with a resampling procedure using MiST scores. Viral overlap was performed as previously described (Davis et al., 2015), and statistical analysis was performed using the hypergeometric test.

Infections and RNAi

Cells were infected with Chlamydia for 1 hr and then incubated for 15–24 hr (primary infection, tubulation or immunoprecipitation) or 72 hr (progeny production). For some experiments, nucodazole or Tc was added 1 hr postinfection. HeLa cells were transfected with siRNAs (Dharmacon) according to manufacturer's protocols and infected with Chlamydia at 48 hr postinfection. Protein depletion was assayed by immunoblot.

Transfections and Immunoprecipitations

Lysates from HeLa cells collected 24 hpi were immunoprecipitated with control IgG or anti-SNX6 antibody using Protein G Dynabeads (Invitrogen). Alternatively, HeLa cells were transfected (Effectene, QIAGEN) according to manufacturer’s protocol and infected with Chlamydia at 48 hr postinfection. Protein depletion was assayed by immunoblot.
